ABSTRACT

Background: Despite growing concern over potential health effects associated with exposures to the endocrine disruptor, bisphenol A (BPA), insufficient information is available on determinants of BPA concentrations among minority populations in the US.

Objectives: To describe concentrations and predictors of BPA in an inner-city longitudinal birth cohort.

Methods: We analyzed spot urines for total BPA collected during pregnancy and child ages 3, 5, and 7 years from African Americans and Dominicans (n=568) enrolled in the Columbia Center for Children’s Environmental Health birth cohort and residing in Northern Manhattan and the South Bronx. Adjusting for specific gravity, generalized estimating equations were used to compare BPA concentrations across paired samples and linear regression analyses were used to determine relationships between BPA, season of sample collection, socio-demographic variables and urinary concentrations of phthalate metabolites.

Results: BPA was detected in >94% of samples. Prenatal concentrations were significantly lower than postnatal concentrations. Geometric means were higher among African Americans compared to Dominicans in prenatal (p=0.008), 5 year (p<0.001) and 7 year (p=0.017) samples. Geometric means at 5 and 7 years were higher (p=0.021, p=0.041 respectively) for children of mothers never married compared to mothers ever married at enrollment. BPA concentrations were correlated with phthalate metabolite concentrations at prenatal, 5 and 7 years (p-values <0.05). Postnatal BPA concentrations were higher in samples collected during the summer.

Conclusions: This study shows widespread BPA exposure in an inner-city minority population. BPA concentration variations were associated with socio-demographic characteristics and other xenobiotics.

1. Introduction

Bisphenol A (BPA), a xenoestrogenic monomer, was originally investigated for efficacy as a synthetic hormone treatment during the 1930s–1940s. Today BPA is used commercially as a key component in manufacturing polycarbonate plastics and epoxy resins. BPA has applications in everyday consumer products such as baby bottles, toys, dental sealants, eyeglass lenses, reusable water bottles, plastic stretch films, consumer electronics, digital media (CDs, DVDs), automobiles, medical equipment, food and beverage can linings and glass jar tops (Vandenbarg et al., 2007, 2010). Approximately 4 million tons of BPA are produced annually (Vandenbarg et al., 2010). Global market prices and demand for polycarbonate are on the rise and expected to grow at an average annual rate of 5.8% to 4.9 million tons by 2015 (CMAI, 2010).

This widespread use has resulted in significant exposures (Calafat et al., 2008). Known routes of exposure include dermal and inhalation, but dietary intake is of primary concern (Wilson et al., 2005; Zalko et al., 2011). BPA has been found in fresh and pre-packed foods, including infant formula in Europe, Asia and the United States (US) (Kuo and Ding, 2004; Noonan et al., 2011; Rudel et al., 2011; Schneider et al., 2010; Vandenbarg et al., 2007, Wilson et al., 2007). Results from a recent study of US preschool children ages 23–64 months, suggest that diet contributes 95% of childhood exposure to BPA and that solid food is a significant contributor (Morgan et al., 2011). Human maternal exposure has been quantified in breast milk, serum, plasma, urine, ovarian follicular fluid, amniotic fluid and placental tissue (Ikezuki et al., 2002; Schönfelder et al.,...
et al., 2010; Matsumoto et al., 2005; Sugiura-Ogasawara et al., 2011; Ikezuki et al., 2002; Padmanabhan et al., 2008; Schöpf et al., 2002). However, there is also evidence that the use of catheters during delivery may introduce BPA into the mother’s body (Vandentorren et al., 2011). The biologic half-life of BPA has long been accepted to be approximately 4 h. To date, there is no conclusive evidence regarding clearance rate of BPA from the developing human fetus or child.

Experimental and preliminary epidemiological studies suggest associations between BPA exposure and numerous adverse health effects, including cardiovascular disease, breast cancer, metabolic disorders, male sexual function, polycystic ovary syndrome, recurrent miscarriages, female adult obesity, endometrial hyperplasia and thyroid effects (Alonso-Magdalena et al., 2010; Crofton, 2008; Hiroi et al., 2004; Lang et al., 2008; Li et al., 2010; Melzer et al., 2010; Matsumoto et al., 2005; Sugiuara-Ogasawara et al., 2005; Takeuchi et al., 2004; Vandenberg et al., 2007). A positive association has been shown between BPA exposure and higher estrogenic gene expression in male adults (Melzer et al., 2011).

There is little prior information on prenatal and early childhood exposure to BPA among minority populations in the US. Much of the current prenatal data comes from Asia and Europe (Casas et al., 2011; Ikezuki et al., 2002; Padmanabhan et al., 2008; Schönfelder et al., 2002; Yamada et al., 2002; Ye et al., 2008, 2009). Both the US National Health and Nutritional Examination Survey (NHANES) and the Canadian Health Measures Survey report on BPA concentrations among different ethnic groups but are limited to analyses of BPA in adults and in children ages 6 years and older (Calafat et al., 2008; Health Canada, 2010). Another study limited to girls aged 6 years and older of multiple ethnicities in the US by Wolff and Teitelbaum had detectable concentrations of BPA in 96% of pregnant women. (Ikezuki et al., 2002; Schönfelder et al., 2002). However, there is also evidence that conjugated BPA can cross the placenta (Vandentorren et al., 2011). The biologic half-life of BPA has long been accepted to be approximately 4 h. To date, there is no conclusive evidence regarding clearance rate of BPA from the developing human fetus or child.

Additionally, little is known about inter-correlations between BPA concentrations and other chemical exposures that might affect childhood development. While Woodruff et al. performed analyses on groups of chemicals in the same chemical classes from NHANES samples, they did not examine the relationships between phenols and phthalates (Woodruff et al., 2011). There is growing concern regarding effects from mixtures of chemical exposures in the literature (Casals-Casas and Deserengne, 2011; Kavlock et al., 1996; Landrigan et al., 2003).

In this paper we report on BPA concentrations in a minority, low income birth cohort of African American and Dominican mothers and children living in New York City. We also identify associations between BPA concentrations and season of sample collection, socio-demographic characteristics and phthalate metabolites, a family of chemicals shown to be weakly associated with BPA in prior studies (Braun et al., 2011a) and which should be considered for confounding effects when analyzing BPA in health outcomes research.

2. Material and methods

2.1. Study design and population

Participants (n=568) were selected from the mothers and newborns longitudinal cohort study of the Columbia Center for Children’s Environmental Health (CCCEH) based in Northern Manhattan and the South Bronx, New York (Peraea et al., 2003; Whyatt et al., 2003). The mother was selected for our analysis if she had a spot urine sample analyzed for BPA prenatally and her child was selected if he or she had at least one sample analyzed at age 3, 5 or 7 years. For the first 3 years of the CCCEH study, enrolled participants were contacted every 3 months after delivery for questionnaire follow-up and every 6 months thereafter, with biological samples collected from the children at ages 3, 5, and 7 years. Biological samples were collected from the children regardless of any prior missed collection intervals. At the time of our analysis, the 7 year old follow-up was not yet complete.

Study protocols for the CCCEH cohort are described elsewhere (Peraea et al., 2003; Whyatt et al., 2003). Briefly, the study enrolled pregnant women 18–35 years old who self-identified as either African American or Dominican and had resided in Northern Manhattan or the South Bronx for at least 1 year before pregnancy. Women were excluded at enrollment if they reported that they smoked cigarettes or used other tobacco products during pregnancy, used illegal drugs, had diabetes, hypertension or known HIV, or had their first prenatal visit after the 20th week of gestation. A 45 min baseline questionnaire was administered to the mother by a trained bilingual interviewer during the third trimester of pregnancy and at each follow-up interval (child age 3, 5 and 7 years). Medical records of the mother and infant at delivery were abstracted by the research staff to ascertain birth outcomes.

2.2. Urinary biomarker collection

In the mothers, urine was collected during the third trimester of pregnancy between 1999 and 2006 (mean gestational age: 34.7 weeks; SD: 3.4). In the children, urine was collected concurrent with the follow-up questionnaires between 1999 and 2010. The samples were all spot urine samples collected at varying times of day. The date, but not the exact time of collection, was consistently available. The total (free plus conjugated) BPA urinary concentrations (ng/ml) were measured at the National Center for Environmental Health, Centers for Disease Control and Prevention (CDC). Urine samples were analyzed using online solid-phase extraction coupled to high-performance liquid chromatography, and detected with isotope-dilution tandem mass spectrometry with peak focusing as previously described (Calafat et al., 2008). The assay limit of detection (LOD) was 0.4 ng/ml. For results below LOD, the value of LOD/2 was substituted where applicable, consistent with prior analyses (Whyatt et al., 2003, 2009). Specific gravity, as a measure of urinary dilution, was quantified at room temperature at Columbia University with a handheld refractometer (PAL 10-S, Atago, Bellevue, WA).

The following phthalate metabolites were also measured in the spot urine samples at CDC as previously described (Kato et al., 2005; Silva et al., 2007): mono-2-ethylhexyl phthalate (MEHP), mono-2-ethyl-5-carboxypentyl phthalate (MECPP), mono-2-ethyl-5-hydroxyhexyl phthalate (MEHHP), mono-2-ethyl-5-oxohexyl phthalate (MEOH), mono-benzyl phthalate (MBzP), mono-3-carboxypropyl phthalate (MCP), mono-n-buty1 phthalate (MBnP), mono-isobutyl phthalate (MIBP) and mono-ethyl phthalate (MEP). The LODs ranged from 0.2 to 1.2 ng/ml for all phthalate metabolites. The value of LOD/2 was assigned to the few phthalate metabolite concentrations below LOD. We multiplied the reported MEP and MBzP concentrations by 0.66 and 0.72, respectively, to correct for the inadequate purity of the analytic standards used (Calafat, personal communication, 2012). Due to a higher rate of non-detectable results, MEHP was dropped from analysis in favor of the other three metabolites of di-2-ethylhexyl-phthalate (DEHP): MECPP; MEHHP and MEOH.

Study procedures, questionnaires and collection of biological samples were explained to each subject at enrollment and a signed consent, approved by the IRB of Columbia University Medical Center and the CDC, was obtained.

2.3. Statistical analysis

BPA concentrations were natural log-transformed and z-scored urinary specific gravity measures were included in regression models as a covariate. Specific gravity values have a very narrow range and cluster tightly around 1.0, which can cause instability in estimating model constants. Specific gravity values were z-score transformed, which does not alter the beta coefficients for the other variables in the model, but does stabilize the estimate of the model constant. Means of the log-transformed BPA data were calculated and exponentiated to calculate geometric mean BPA concentrations. Specific gravity adjusted/log-transformed urinary specific gravity values were 2-scored and then natural-log transformed.

To determine Pearson correlations between BPA samples at each collection (i.e. prenatal vs. each child sample; child vs. each later child sample) we used the formula: BPA × [mean for age-adjusted-transformed ‘LN(BPA)’]/[mean for age-adjusted-transformed ‘LN(BPA)’] – 1)/[(individual specific gravity – 1)/1] (Hauer et al., 2004). For example, the BPA data was first corrected with prenatal specific gravity in the algorithm and then natural-log transformed.
Socio-demographic predictors of BPA concentrations at each time point were assessed using two separate regression analyses. The first was a series of linear regression models including one socio-demographic predictor variables as well as standardized specific gravity as the correction covariate. The second was a series of linear regression GLM models including season of collection as a categorical model with summer as the reference group. Socio-demographic variables we included were: race/ethnicity classified as African American or Dominican, child’s sex, income classified as above or below $20,000 per year, marriage status classified as never or ever married at enrollment; maternal education classified as no high school diploma or high school diploma or higher education level, and breastfeeding status classified as ever or never within 3 months of the child’s birth. Season of urine collection was coded using June to August (summer) as the reference group with 3 month units composing Fall (September–November), Winter (December–February) and Spring (March–May) (Wolff et al., 2010). Partial reference group with 3 month units composing Fall (September–November), Winter (December–February) and Spring (March–May) (Wolff et al., 2010). Partial reference group with 3 month units composing Fall (September–November), Winter (December–February) and Spring (March–May) (Wolff et al., 2010). Partial reference group with 3 month units composing Fall (September–November), Winter (December–February) and Spring (March–May) (Wolff et al., 2010). Partial reference group with 3 month units composing Fall (September–November), Winter (December–February) and Spring (March–May) (Wolff et al., 2010). Partial reference group with 3 month units composing Fall (September–November), Winter (December–February) and Spring (March–May) (Wolff et al., 2010). Partial reference group with 3 month units composing Fall (September–November), Winter (December–February) and Spring (March–May) (Wolff et al., 2010). Partial reference group with 3 month units composing Fall (September–November), Winter (December–February) and Spring (March–May) (Wolff et al., 2010).

We considered results with \( p < 0.05 \) to be statistically significant. All of our analyses were performed using PASW Statistics version 18.0 (SPSS Inc., Chicago, IL, USA).

### 3. Results

#### 3.1. Study population characteristics

Of the 568 participants, we measured BPA concentration in \( n=375 \) prenatal samples, \( n=408 \) age 3 year samples, \( n=401 \) age 5 year samples, and \( n=318 \) age 7 year samples. Demographic characteristics during the prenatal period are presented in Table 1. There were no significant differences in demographic characteristics for those children with all 3 childhood urine samples analyzed compared to those with fewer than 3 childhood samples.

BPA was detected in 94% of prenatal samples, 98% of 3 year and 5 year samples, and 96% of 7 year samples. BPA concentrations (ng/ml) are presented in Table 2. The geometric mean BPA remained stable in prenatal samples collected between 1999 and 2006 and a temporal trend was not observed (Fig. 1, Supplemental Table S1). Similarly, for each of the follow-up samples collected from 2001 to 2009 (age 3), 2003 to 2010 (age 5) and 2005 to 2010 (age 7) there were no temporal trends in geometric mean BPA concentrations (Supplemental Table S2).

Maternal prenatal BPA concentrations were not correlated with any of the child concentrations (all \( p \)-values \( \geq 0.40 \)). Among children, only the age 3 and 7 year concentrations were weakly correlated (\( r = 0.164, \ p = 0.012 \)) while the 3 and 5 year concentrations and 5 and 7 year concentrations did not correlate (\( p = 0.823, \ p = 0.079 \) respectively). Maternal prenatal BPA concentrations were significantly lower than those of their children at all ages (see Table 2). Child BPA concentrations at age 3 years were significantly higher than repeat samples at ages 5 and 7 years. However, BPA concentrations did not significantly differ at ages 5 and 7 years. When complementary analyses were done in subjects with BPA concentrations at all three postnatal ages \( (n = 227) \) to account for the differing sample sizes at ages 3, 5 and 7 years the correlation and GEE results were similar.

#### 3.2. Socio-demographic predictors of BPA

Table 3 shows BPA concentration by demographic characteristics and season. Adjusting for specific gravity, BPA geometric means concentrations were higher among African American as compared to Dominicans in prenatal (\( p = 0.008 \)) and 7 year (\( p = 0.017 \)) samples but not in 3 year samples (\( p = 0.89 \) (Table 3). Geometric means at 5 and 7 years were higher (\( p = 0.021, \ p = 0.041 \) respectively) for children of mothers never married at cohort enrollment compared to mothers ever married at cohort enrollment. Comparisons of BPA concentrations by child’s sex, maternal education at enrollment, and household income at enrollment did not reveal significant differences at any assessment interval.

#### 3.3. Season of collection predictors of BPA

After adjusting for specific gravity, calendar season of urine collection predicted log-transformed BPA concentration. Geometric means for urine collections during the summer at ages 3, 5 and 7 year (\( p = 0.001 \) respectively) for children of mothers never married at cohort enrollment compared to mothers ever married at cohort enrollment. Comparisons of BPA concentrations by child’s sex, maternal education at enrollment, and household income at enrollment did not reveal significant differences at any assessment interval.

* Missing from all subjects: maternal education \( n = 9 \), marital status \( n = 2 \), household income \( n = 39 \), breastfed \( n = 100 \), gestational age \( n = 4 \).
5 and 7 years were consistently higher than those collected in all other seasons (p-values range: 0.001–0.034) (Table 3). When the non-summer seasons were collapsed into a single category, regression analyses showed that BPA concentrations in samples collected in summer months remained significantly higher than concentrations in samples collected in non-summer months: 3 years: β: 0.4 ng/ml, CI: (0.65, 0.25), p < 0.001; 5 years: β: 0.30 ng/ml, CI: (0.50, 0.11), p = 0.002; 7 years: β: 0.50 ng/ml, CI: (0.72, 0.29), p < 0.001.

3.4. Phthalate correlations

Table 4 presents partial correlation coefficients for natural log-transformed BPA compared to natural log-transformed urinary metabolites of phthalates after adjustment for specific gravity. Prenatal BPA concentrations were weakly but significantly correlated with phthalate metabolite concentrations after adjusting for specific gravity. Similar to the prenatal findings, childhood BPA concentrations were weakly but significantly correlated with all urinary phthalate metabolite concentrations after adjusting for specific gravity at ages 3, 5 and 7 years. The highest correlations were with the DEHP metabolites at age 3 years.

4. Discussion

Results show BPA to be a pervasive contaminant with 94% or higher detection rates in this study population of inner-city mothers and children. We found that geometric means for maternal prenatal BPA concentrations were significantly lower than paired children’s postnatal concentrations. BPA in pregnant women may be temporarily diverted from the excretory process due to transfer across the placenta. Human placenta does not act as a barrier to BPA (Schönfelder et al., 2002). Studies of radiolabeled-BPA in pregnant CD1 mice determined that after 24 h, only 6% of BPA was excreted in urine while a disaccharide conjugate of BPA accounted for 60%, 20% and 10% of radioactivity in placenta, amniotic fluid and fetuses, respectively (Zalko et al., 2003).
In humans, placenta has only a syncytiotrophoblast monolayer separating the maternal and fetal blood vessels as opposed to the mouse placenta which has three layers. Early in pregnancy, amniotic fluid is comparable to maternal or fetal plasma and may be composed of secretions from the umbilical cord, placental membrane and developing epithelium (Beall et al., 2007; Underwood et al., 2005). While the literature has yet to describe in humans, there remains the possibility that pregnant women may have less BPA in their urine due to transfer across the placenta. Alternatively, lower total BPA urinary concentration in the mothers than in their children may be related to the fact that diet is the main pathway of exposure to BPA (Morgan et al., 2011) and children eat more relative to body weight than adults (US EPA, 2011). Such a trend has been observed for other non-persistent chemicals to which diet is the main source of exposure (CDC, 2012). In contrast, some animal pharmacokinetic evidence suggests that total daily human exposure to BPA cannot be from diet alone and is much higher than previously understood (Taylor et al., 2011).

Our unadjusted geometric means are similar to data from two other studies comparing prenatal and childhood BPA concentrations. A European Spanish cohort of mothers and their 4 year old children, reported lower urinary concentrations of BPA in spot urine samples collected prenatally from the mothers as compared to their children (2.2 ng/mL, n = 120 vs. 4.2 ng/mL, n = 30, p < 0.05, respective medians) (Casas et al., 2011). In a Cincinnati, Ohio study of 240 mother–child dyad spot urine samples, the mean prenatal BPA concentration was 2.0 µg/L and the childhood mean of ages 1, 2, and 3 years was 4.1 µg/L, while the median age 3 year BPA concentration was 2.6 µg/L (Braun et al., 2011b).

Our overall prenatal BPA geometric mean of 1.8 ng/mL is in accordance with findings from other investigators. In a US study looking at repeated measures of BPA in 249 women both prenatally and postnatally, Braun et al. (2011b) found median BPA concentrations of 1.8 µg/L (16 weeks), 1.7 µg/L (26 weeks) and 1.2 µg/L (at birth). Using NHANES data, Woodruff et al. (2011) reported a lower geometric mean in pregnant women compared to non-pregnant women (2.53 µg/L, n = 86 vs. 2.89 µg/L, n = 489, respectively). After adjusting for creatinine and socio-demographics (age, race/ethnicity, education, smoking, parity, BMI, albumin, duration of fasting prior to sample collection) the BPA concentration disparity increased between pregnant women (1.63 µg/L, n = 72) and non-pregnant women (2.83 µg/L, n = 371) (Woodruff et al., 2011).

Due to the metabolic characteristics of pregnant women and young children, we controlled for urinary specific gravity as opposed to creatinine in our regression and correlation analyses and this could result in some differences across studies. Renal clearance of creatinine is directly proportional to and dependent on glomerular filtration, such that changes in renal clearance that commonly occur during pregnancy could also cause changes in creatinine concentrations (Jatlow et al., 2003; Mahalingaiah et al., 2008). Creatinine, a product of muscle metabolism, relies on the liver and the kidney which are still maturing in children. Childhood levels of creatinine tend to be lower with more variability over time compared to levels in non-elderly adults. Creatinine comparisons in the NHANES III (1988–1994) study describe a mean of 102.1 mg/dL in children ages 6–11 years, whereas adult means were consistently higher by decade of age from 20 to 49 years (Braun et al., 2005). Little is known about BPA renal clearance during human pregnancy. Specific gravity is a unit-less ratio of the density of urine to the density of water, dependent on fluid intake, renal perfusion and renal function and thus should be less influenced by muscle mass and muscle retention.

At age 3 years, the children in our study had significantly higher BPA concentrations than they did at follow-up ages 5 and 7 years, a difference that may be related to changes in behavior as children age. While young children tend to have greater oral contact with their world than older children and adults, diet should still be considered the primary route of BPA exposure in young children (Reed et al., 1999). It is known that children between the ages of 3 and 6 years eat more relative to body weight than adults (US EPA, 2011). Additionally, children under the age of 6 years tend to have less varied diets (Goldman, 1995). Diet in preschool children may be more dependent on the feeding behaviors of their mothers whereas school-aged children are able to make food choices outside the presence of their mothers. Adult pregnant female eating behaviors are also likely to be different than those of children.

In our study population, African Americans had consistently significantly higher BPA concentrations than Dominican Americans, except among 3 year olds where BPA was elevated for African Americans but not significantly. Additionally we saw significantly higher BPA concentrations than they did at follow-up ages 5 and 7 years, a difference that may be related to changes in behavior as children age. While young children tend to have greater oral contact with their world than older children and adults, diet should still be considered the primary route of BPA exposure in young children (Reed et al., 1999). It is known that children between the ages of 3 and 6 years eat more relative to body weight than adults (US EPA, 2011). Additionally, children under the age of 6 years tend to have less varied diets (Goldman, 1995). Diet in preschool children may be more dependent on the feeding behaviors of their mothers whereas school-aged children are able to make food choices outside the presence of their mothers. Adult pregnant female eating behaviors are also likely to be different than those of children.

In our study population, African Americans had consistently significantly higher BPA concentrations than Dominican Americans, except among 3 year olds where BPA was elevated for African Americans but not significantly. Additionally we saw significantly higher BPA concentrations among older children of never married mothers compared to older children of ever married mothers. This suggests that BPA concentrations may vary by socioeconomic status. However, we did not see any differences based on household income nor maternal education. In contrast, other studies have found BPA concentration to be negatively associated with income and maternal education (Calafat et al., 2008; Braun et al., 2011b). Little is known about how dietary differences across race/ethnicity and maternal characteristics may affect BPA exposures in pregnancy or childhood. Our results have implications for guiding socio-demographic considerations in future health effects studies of BPA exposures.

We found postnatal BPA concentrations to be higher during the summer months than during the rest of the year. This could be due to different dietary patterns among children during the summer relative to other seasons. It could also be related to diurnal variation in renal clearance of BPA by season. This finding is consistent with previously reported BPA urinary geometric

Acknowledgments

Funding for the study is provided by the National Institute of Environmental Health Sciences (Grant 1R2CE018784), the US Environmental Protection Agency (Grant RD-83214101), the National Institute of Health (Grant P01ES09600), and the John and Wendy Neu Family Foundation. The authors gratefully acknowledge the technical assistance of Manori Silva, Ella Samanadar, Jim Preau, Xiaoyun Ye, Ryan Hennings, Xiaoliu Zhou and Lily Jia for measuring the urinary concentrations of phthalate metabolites and bisphenol A. We are grateful to the participating families who have so generously contributed their time and effort to the study. The findings and conclusions in this paper are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.
